Midterm results

- Mean: 42.39, median: 44
• Systems students should insist on a CDF!
• Recall we will have a resurrection final
  - Don’t panic if you didn’t do well on midterm
  - But make sure you understand all the answers
  - There may be questions on same topics on the final

• …but only if you got $> 0$ on the midterm
  - You should withdraw from class if you did not take the midterm

2. Exploiting program behavior
3. Allocator designs
4. User-level MMU tricks
5. Garbage collection
Dynamic memory allocation

• Almost every useful program uses it
  - Gives wonderful functionality benefits
    ▶ Don’t have to statically specify complex data structures
    ▶ Can have data grow as a function of input size
    ▶ Allows recursive procedures (stack growth)
  - But, can have a huge impact on performance

• Today: how to implement it
  - Lecture based on [Wilson]

• Some interesting facts:
  - Two or three line code change can have huge, non-obvious impact on how well allocator works (examples to come)
  - Proven: impossible to construct an "always good" allocator
  - Surprising result: memory management still poorly understood
- Satisfy arbitrary set of allocation and frees.
- Easy without free: set a pointer to the beginning of some big chunk of memory ("heap") and increment on each allocation:

  - Problem: free creates holes ("fragmentation")
  - Result? Lots of free space but cannot satisfy request!
More abstractly

- **What an allocator must do?**
  - Track which parts of memory in use, which parts are free
  - Ideal: no wasted space, no time overhead

- **What the allocator cannot do?**
  - Control order of the number and size of requested blocks
  - Know the number, size, or lifetime of future allocations
  - Move allocated regions (bad placement decisions permanent)

- **The core fight: minimize fragmentation**
  - App frees blocks in any order, creating holes in “heap”
  - Holes too small? cannot satisfy future requests
What is fragmentation really?

- Inability to use memory that is free
- Two factors required for fragmentation
  1. Different lifetimes—if adjacent objects die at different times, then fragmentation:

        ▶ If all objects die at the same time, then no fragmentation:

  2. Different sizes: If all requests the same size, then no fragmentation (that’s why no external fragmentation with paging):
Important decisions

• **Placement choice:** where in free memory to put a requested block?
  - Freedom: can select any memory in the heap
  - Ideal: put block where it won’t cause fragmentation later
    (impossible in general: requires future knowledge)

• **Split free blocks to satisfy smaller requests?**
  - Fights internal fragmentation
  - Freedom: can choose any larger block to split
  - One way: choose block with smallest remainder (best fit)

• **Coalescing free blocks to yield larger blocks**

  \[
  \begin{array}{ccc}
  20 & 10 & 30 \\
  \end{array}
  \rightarrow
  \begin{array}{cc}
  30 & 30 \\
  \end{array}
  \]
  - Freedom: when to coalesce (deferring can save work)
  - Fights external fragmentation
Impossible to “solve” fragmentation

- If you read allocation papers to find the best allocator
  - All discussions revolve around tradeoffs
  - The reason? There cannot be a best allocator

- Theoretical result:
  - For any possible allocation algorithm, there exist streams of allocation and deallocation requests that defeat the allocator and force it into severe fragmentation.

- How much fragmentation should we tolerate?
  - Let $M =$ bytes of live data, $n_{\text{min}} =$ smallest allocation, $n_{\text{max}} =$ largest – How much gross memory required?
  - Bad allocator: $M \cdot \left(\frac{n_{\text{max}}}{n_{\text{min}}}\right)$
    - E.g., only ever use a memory location for a single size
    - E.g., make all allocations of size $n_{\text{max}}$ regardless of requested size
  - Good allocator: $\sim M \cdot \log\left(\frac{n_{\text{max}}}{n_{\text{min}}}\right)$
Pathological examples

• Suppose heap currently has 7 20-byte chunks
  
  20 20 20 20 20 20 20

  - What’s a bad stream of frees and then allocates?

• Given a 128-byte limit on malloced space
  
  - What’s a really bad combination of mallocs & frees?

• Next: two allocators (best fit, first fit) that, in practice, work pretty well
  
  - “pretty well” = ~20% fragmentation under many workloads
Pathological examples

• Suppose heap currently has 7 20-byte chunks

| 20 | 20 | 20 | 20 | 20 | 20 | 20 |

- What’s a bad stream of frees and then allocates?
- Free every other chunk, then alloc 21 bytes

• Given a 128-byte limit on malloced space

- What’s a really bad combination of mallocs & frees?

• Next: two allocators (best fit, first fit) that, in practice, work pretty well

- “pretty well” = ~20% fragmentation under many workloads
Pathological examples

• Suppose heap currently has 7 20-byte chunks

| 20 | 20 | 20 | 20 | 20 | 20 | 20 |

- What’s a bad stream of frees and then allocates?
- Free every other chunk, then alloc 21 bytes

• Given a 128-byte limit on malloced space

- What’s a really bad combination of mallocs & frees?
- Malloc 128 1-byte chunks, free every other
- Malloc 32 2-byte chunks, free every other (1- & 2-byte) chunk
- Malloc 16 4-byte chunks, free every other chunk...

• Next: two allocators (best fit, first fit) that, in practice, work pretty well

- “pretty well” = ~20% fragmentation under many workloads
Best fit

- **Strategy:** minimize fragmentation by allocating space from block that leaves smallest fragment
  - Data structure: heap is a list of free blocks, each has a header holding block size and a pointer to the next block
    
    ![Diagram](image)

    - Code: Search freelist for block closest in size to the request. (Exact match is ideal)
    - During free (usually) coalesce adjacent blocks

- **Potential problem:** Sawdust
  - Remainder so small that over time left with “sawdust” everywhere
  - Fortunately not a problem in practice
Best fit gone wrong

- Simple bad case: allocate $n, m$ ($n < m$) in alternating orders, free all the $n$s, then try to allocate an $n + 1$

- Example: start with 99 bytes of memory
  - alloc 19, 21, 19, 21, 19
    
    | 19 | 21 | 19 | 21 | 19 |
    
  - free 19, 19, 19:
    
    | 19 | 21 | 19 | 21 | 19 |
    
  - alloc 20? Fails! (wasted space = 57 bytes)

- However, doesn’t seem to happen in practice
First fit

• **Strategy: pick the first block that fits**
  - Data structure: free list, sorted LIFO, FIFO, or by address
  - Code: scan list, take the first one

• **LIFO: put free object on front of list.**
  - Simple, but causes higher fragmentation
  - Potentially good for cache locality

• **Address sort: order free blocks by address**
  - Makes coalescing easy (just check if next block is free)
  - Also preserves empty/idle space (locality good when paging)

• **FIFO: put free object at end of list**
  - Gives similar fragmentation as address sort, but unclear why
• Storage management example of subtle impact of simple decisions

• LIFO first fit seems good:
  - Put object on front of list (cheap), hope same size used again (cheap + good locality)

• But, has big problems for simple allocation patterns:
  - E.g., repeatedly intermix short-lived $2n$-byte allocations, with long-lived $(n + 1)$-byte allocations
  - Each time large object freed, a small chunk will be quickly taken, leaving useless fragment. Pathological fragmentation
First fit: Nuances

• **First fit sorted by address order, in practice:**
  - Blocks at front preferentially split, ones at back only split when no larger one found before them
  - Result? Seems to roughly sort free list by size
  - So? Makes first fit operationally similar to best fit: a first fit of a sorted list = best fit!

• **Problem: sawdust at beginning of the list**
  - Sorting of list forces a large requests to skip over many small blocks. Need to use a scalable heap organization

• **Suppose memory has free blocks:**
  - If allocation ops are 10 then 20, best fit wins
  - When is FF better than best fit?
First fit: Nuances

- **First fit sorted by address order, in practice:**
  - Blocks at front preferentially split, ones at back only split when no larger one found before them
  - Result? Seems to roughly sort free list by size
  - So? Makes first fit operationally similar to best fit: a first fit of a sorted list = best fit!

- **Problem: sawdust at beginning of the list**
  - Sorting of list forces a large requests to skip over many small blocks. Need to use a scalable heap organization

- **Suppose memory has free blocks:**
  - If allocation ops are 10 then 20, best fit wins
  - When is FF better than best fit?
  - Suppose allocation ops are 8, 12, then 12 → first fit wins
Some worse ideas

- **Worst-fit:**
  - Strategy: fight against sawdust by splitting blocks to maximize leftover size
  - In real life seems to ensure that no large blocks around

- **Next fit:**
  - Strategy: use first fit, but remember where we found the last thing and start searching from there
  - Seems like a good idea, but tends to break down entire list

- **Buddy systems:**
  - Round up allocations to power of 2 to make management faster
  - Result? Heavy internal fragmentation
Outline

1. Malloc and fragmentation
2. Exploiting program behavior
3. Allocator designs
4. User-level MMU tricks
5. Garbage collection
Known patterns of real programs

- So far we’ve treated programs as black boxes.
- Most real programs exhibit 1 or 2 (or all 3) of the following patterns of alloc/dealloc:
  - **Ramps**: accumulate data monotonically over time
  - **Peaks**: allocate many objects, use briefly, then free all
  - **Plateaus**: allocate many objects, use for a long time
Pattern 1: ramps

- In a practical sense: ramp = no free!
  - Implication for fragmentation?
  - What happens if you evaluate allocator with ramp programs only?
Pattern 2: peaks

- Peaks: allocate many objects, use briefly, then free all
  - Fragmentation a real danger
  - What happens if peak allocated from contiguous memory?
  - Interleave peak & ramp? Interleave two different peaks?
Exploiting peaks

- Peak phases: allocate a lot, then free everything
  - Change allocation interface: allocate as before, but only support free of everything all at once
  - Called “arena allocation”, “obstack” (object stack), or alloca/procedure call (by compiler people)

- Arena = a linked list of large chunks of memory
  - Advantages: alloc is a pointer increment, free is “free”
    No wasted space for tags or list pointers

![Diagram of arena allocation]
Pattern 3: Plateaus

- Plateaus: allocate many objects, use for a long time
  - What happens if overlap with peak or different plateau?

trace of perl running a string processing script
Fighting fragmentation

- Segregation = reduced fragmentation:
  - Allocated at same time \(\sim\) freed at same time
  - Different type \(\sim\) freed at different time

- Implementation observations:
  - Programs allocate a small number of different sizes
  - Fragmentation at peak usage more important than at low usage
  - Most allocations small (\(<\ 10\) words)
  - Work done with allocated memory increases with size
  - Implications?
1. Malloc and fragmentation
2. Exploiting program behavior
3. Allocator designs
4. User-level MMU tricks
5. Garbage collection
Slab allocation [Bonwick]

- Kernel allocates many instances of same structures
  - E.g., a 1.7 kB `task_struct` for every process on system
- Often want contiguous *physical* memory (for DMA)
- Slab allocation optimizes for this case:
  - A slab is multiple pages of contiguous physical memory
  - A cache contains one or more slabs
  - Each cache stores only one kind of object (fixed size)
- Each slab is **full**, **empty**, or **partial**
- E.g., need new `task_struct`?
  - Look in the `task_struct` cache
  - If there is a partial slab, pick free `task_struct` in that
  - Else, use empty, or may need to allocate new slab for cache
- Advantages: speed, and no internal fragmentation
Simple, fast segregated free lists

- Array of free lists for small sizes, tree for larger
  - Place blocks of same size on same page
  - Have count of allocated blocks: if goes to zero, can return page

- Pro: segregate sizes, no size tag, fast small alloc

- Con: worst case waste: 1 page per size even w/o free, After pessimal free: waste 1 page per object

- TCMalloc [Ghemawat] is a well-documented malloc like this
  - Also uses “thread caching” to reduce coherence misses
Typical space overheads

- Free list bookkeeping and alignment determine minimum allocatable size:
- If not implicit in page, must store size of block
- Must store pointers to next and previous freelist element

```
| 12 | 16 |
```

- Allocator doesn’t know types
  - Must align memory to conservative boundary

- Minimum allocation unit? Space overhead when allocated?
  [demo mtest]
Getting more space from OS

- On Unix, can use `sbrk`
  - E.g., to activate a new zero-filled page:

```c
/* add nbytes of valid virtual address space */
void *get_free_space(size_t nbytes) {
  void *p = sbrk(nbytes);
  if (p == (void *) -1)
    error("virtual memory exhausted");
  return p;
}
```

- For large allocations, `sbrk` a bad idea
  - May want to give memory back to OS
  - Can’t with `sbrk` unless big chunk last thing allocated
  - So allocate large chunk using `mmap`’s `MAP_ANON`
1. Malloc and fragmentation
2. Exploiting program behavior
3. Allocator designs
4. User-level MMU tricks
5. Garbage collection
Faults + resumption = power

- Resuming after fault lets us emulate many things
  - “All problems in CS can be solved by another layer of indirection”

- Example: sub-page protection

- To protect sub-page region in paging system:

  - Set entire page to most restrictive permission; record in PT

  - Any access that violates permission will cause a fault
  - Fault handler checks if page special, and if so, if access allowed
  - Allowed? Emulate write (“tracing”), otherwise raise error
More fault resumption examples

- **Emulate accessed bits:**
  - Set page permissions to “invalid”.
  - On any access will get a fault: Mark as accessed
- **Avoid save/restore of floating point registers**
  - Make first FP operation cause fault so as to detect usage
- **Emulate non-existent instructions:**
  - Give inst an illegal opcode; OS fault handler detects and emulates fake instruction
- **Run OS on top of another OS!**
  - Slam OS into normal process
  - When does something “privileged,” real OS gets woken up with a fault.
  - If operation is allowed, do it or emulate it; otherwise kill guest
  - IBM’s VM/370. Vmware (sort of)
Not just for kernels

• User-level code can resume after faults, too. Recall:
  - `mprotect` – protects memory
  - `sigaction` – catches signal after page fault
  - Return from signal handler restarts faulting instruction

• Many applications detailed by [Appel & Li](#)

• Example: concurrent snapshotting of process
  - Mark all of process’s memory read-only with `mprotect`
  - One thread starts writing all of memory to disk
  - Other thread keeps executing
  - On fault – write that page to disk, make writable, resume
Virtual memory allows us to go to memory or disk

- But, can use the same idea to go anywhere! Even to another computer. Page across network rather than to disk. Faster, and allows network of workstations (NOW)
Persistent stores

- Idea: Objects that persist across program invocations
  - E.g., object-oriented database; useful for CAD/CAM type apps
- Achieve by memory-mapping a file
  - Write your own “malloc” for memory in a file
- But only write changes to file at end if commit
  - Use dirty bits to detect which pages must be written out
  - Or emulate dirty bits with `mprotect/sigaction` (using write faults)
- On 32-bit machine, store can be larger than memory
  - But single run of program won’t access > 4GB of objects
  - Keep mapping of 32-bit memory pointers ↔ 64-bit disk offsets
  - Use faults to bring in pages from disk as necessary
  - After reading page, translate pointers—known as swizzling
Outline

1. Malloc and fragmentation
2. Exploiting program behavior
3. Allocator designs
4. User-level MMU tricks
5. Garbage collection
Garbage collection

• In safe languages, runtime knows about all pointers
  - So can move an object if you change all the pointers

• What memory locations might a program access?
  - Any globals or objects whose pointers are currently in registers
  - Recursively, any pointers in objects it might access
  - Anything else is unreachable, or garbage; memory can be re-used

• Example: stop-and-copy garbage collection
  - Memory full? Temporarily pause program, allocate new heap
  - Copy all objects pointed to by registers into new heap
    ▶ Mark old copied objects as copied, record new location
  - Start scanning through new heap. For each pointer:
    ▶ Copied already? Adjust pointer to new location
    ▶ Not copied? Then copy it and adjust pointer
  - Free old heap—program will never access it—and continue
Concurrent garbage collection

- **Idea:** Stop & copy, but without the stop
  - *Mutator* thread runs program, *collector* concurrently does GC

- **When collector invoked:**
  - Protect from space & unscanned to space from mutator
  - Copy objects in registers into *to space*, resume mutator
  - All pointers in scanned *to space* point to *to space*
  - If mutator accesses unscanned area, fault, scan page, resume

(See [Appel & Li].)
Heap overflow detection

- Many GCed languages need fast allocation
  - E.g., in lisp, constantly allocating cons cells
  - Allocation can be as often as every 50 instructions

- Fast allocation is just to bump a pointer

```c
char *next_free;
char *heap_limit;

void *alloc (unsigned size) {
    if (next_free + size > heap_limit) /* 1 */
        invoke_garbage_collector (); /* 2 */
    char *ret = next_free;
    next_free += size;
    return ret;
}
```

- But would be even faster to eliminate lines 1 & 2!
Heap overflow detection 2

- Mark page at end of heap inaccessible
  - `mprotect (heap_limit, PAGE_SIZE, PROT_NONE);`

- Program will allocate memory beyond end of heap

- Program will use memory and fault
  - Note: Depends on specifics of language
  - But many languages will touch allocated memory immediately

- Invoke garbage collector
  - Must now put just allocated object into new heap

- Note: requires more than just resumption
  - Faulting instruction must be resumed
  - But must resume with different target virtual address
  - Doable on most architectures since GC updates registers
Reference counting

- **Seemingly simpler GC scheme:**
  - Each object has “ref count” of pointers to it
  - Increment when pointer set to it
  - Decremented when pointer killed
    (C++ destructors handy—c.f. `shared_ptr`)

  ```
  void foo(bar c) {
    bar a b;
    a = c; // c.refcnt++
    b = a; // a.refcnt++
    a = 0; // c.refcnt--
    return; // b.refcnt--
  }
  ```

  - ref count == 0? Free object

- **Works well for hierarchical data structures**
  - E.g., pages of physical memory
Reference counting pros/cons

- **Circular data structures always have ref count > 0**
  - No external pointers means lost memory
- **Can do manually w/o PL support, but error-prone**
- **Potentially more efficient than real GC**
  - No need to halt program to run collector
  - Avoids weird unpredictable latencies
- **Potentially less efficient than real GC**
  - With real GC, copying a pointer is cheap
  - With refcounts, must update count each time & possibly take lock (but C++11 `std::move` can avoid overhead)
Ownership types

- Another approach: avoid GC by exploiting type system
  - Use ownership types, which prohibit copies

- You can move a value into a new variable (e.g., copy pointer)
  - But then the original variable is no longer usable

- You can **borrow** a value by creating a pointer to it
  - But must prove pointer will not outlive borrowed value
  - And can’t use original unless both are read-only (to avoid races)

- Ownership types available now in **Rust** language
  - First serious competitor to C/C++ for OSes, browser engines

- C++11 does something similar but weaker with unique types
  - `std::unique_ptr`, `std::unique_lock`, ...
  - Can `std::move` but not copy these
